7.6. Barrow, Alaska

UV data from Barrow differ from the austral high latitude sites in several ways. For example, the "ozone-sensitive" data products, particularly biologically effective dose-rates and the integral around 300 nm, show much smaller short-term variability than at the austral sites due to less severe ozone depletion in the Arctic.

In Figure 7.6.1, recent column ozone data from the Ozone Monitoring Instrument (OMI) are compared with ozone records from the years 1991-2007. Ozone columns are generally higher and have a larger variability during spring than autumn. Ozone levels varied about the long-term average. Distinct drops in total ozone were observed on 4/4/08, 5/4/08, 5/21/08, 7/16/08, 2/23/09, several days around 4/29/09, 5/20/09, and 7/8/09.

Low ozone values in February and March occur at times when solar elevations are still low, and the effect on absolute UV levels is therefore small. In contrast, days with low ozone values in April - July lead to marked spikes in measurements of spectral irradiance integrated over 298.51 - 303.03 nm (Figure 7.6.2). For example, on 4/29/09, values of this integral were 2.8 times larger than the long-term average.

The daily maximum UV Index (Figure 7.6.3) is considerably less affected by total ozone than the 298.51 - 303.03 nm irradiance integral. Most day-to-day variability is introduced by clouds. The highest UV Index of 4.0 was measured on 5/19/09.

Figure 7.6.4 and Figure 7.6.5 show the annual cycles of DNA- and erythemally-weighted daily dose, respectively. Daily irradiation in the 400-600 nm band is shown in Figure 7.6.6. Visible radiation is much more affected by clouds during summer and autumn than during spring.

Factors affecting the annual cycles in UV and visible radiation at Barrow have recently been analyzed in great detail (*Bernhard et al.*, 2007). The annual ozone cycle was found to be the dominant parameter modifying UV-B irradiance, but the combined effects of albedo and clouds compensate for most of the ozone influence. High surface albedo caused by snow cover may increase UV irradiance by up to 57%. Aerosols lead to reductions of 5% typically, but larger reduction was observed during Arctic haze events, particularly during spring. For erythemal irradiance, and measurements in the UV-A and visible, annual cycles of albedo and clouds are responsible for a pronounced seasonal asymmetry.

An example of the different characteristics of DNA-damaging and visible radiation is shown in Figure 7.6.7. Daily irradiation in the 400-600 nm spectral range is not centered at the summer solstice but shifted by about 15 days towards spring. The DNA curve on the other hand is nearly symmetrical with respect to solstice. The reason for this distinct difference can be explained as follows: surface albedo is larger and clouds are less prevalent in spring than in autumn. This enhances radiation levels in spring and is the reason of the apparent shift of measurements in the visible. Higher albedo and less cloudiness also leads to larger DNA-damaging radiation, but the larger total ozone column in spring (Figure 7.6.1) compensates the enhancement. As a consequence, DNA-damaging radiation is of similar magnitude in spring and autumn.

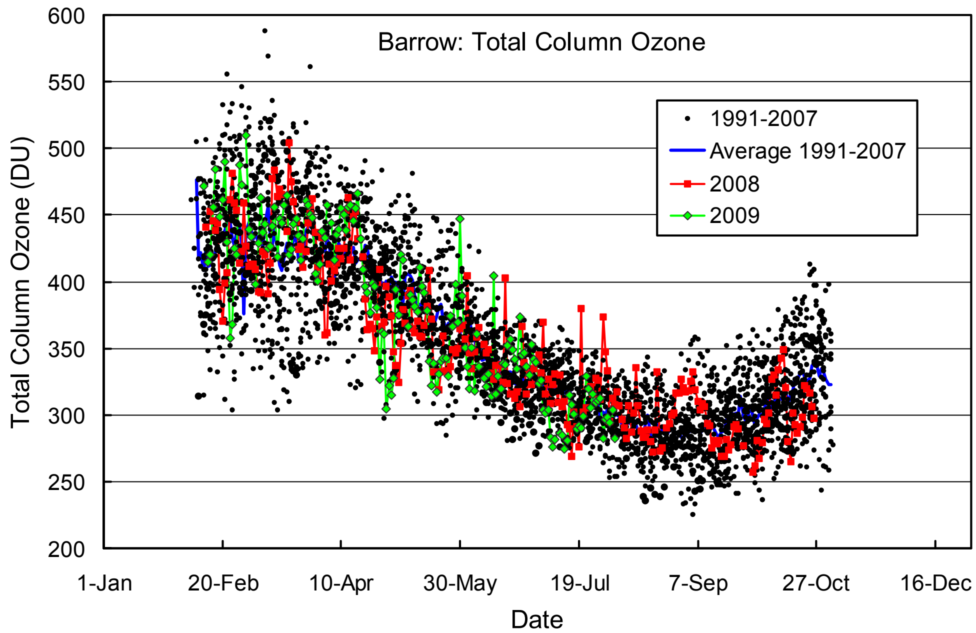

Figure 7.6.1. *Total column ozone at Barrow. OMI measurements from 2008 and 2009 are contrasted with ozone data from prior years recorded by TOMS on Nimbus-7 (1991-1993), Earth Probe (1996-2004), and OMI (2005-2007) satellites. TOMS data are from the Version 8 data set.*
